

1. (20 points) Show what Scheme will display or do if you enter each expression to the top-level interpreter (i.e., at the STk> prompt).

(i) (list 'list)

✓ (list)

(ii) (car (car (list 'a)))

✓ Error

(iii) (first '(word 1 2 3))

-1 word

(iv) ((lambda () (/ 3 1)))

-2

(v) (define (f) (g))
(define (g) f)
(f)

-1 f closure

(vi) ((define (square x) (* x x)) 2)

✓ Error (calling define again for 2)

(vii) ((lambda (x y) x) '(1 2))

-2 (1 2)

(viii) (cons (cons 1 '()) (cons 2 '()))

-1 (1 2)

(ix) ((lambda (foo x y) (foo x y)) word 'x 'y)

✓ xy

(x) (let ((+ 0) (x +) (y 1))
(x + y))

-2 Error (+) isn't a variable

2. (10 points) This question builds on the Twenty-one game from project 1. Instead of representing a card by a word consisting of a number or letter and a letter for the suit, we are going to use a pair. The pair will include a number or letter for the rank of the card (i.e., 2, 3, ..., 10, j, q, k, or a) and a letter for the suit (i.e., c, d, h, or s).

For example the 4 of hearts and the king of diamonds will be represented as follows:

```
(cons 4 'h)
(cons 'k 'd)
```

- (i) (2 points) Write a function `make-card` that takes a rank and suit and returns a pair representing the card.

```
(define (make-card rank suit)
  (cons rank suit))
```

(+2)

- (ii) (4 points) Write two accessor functions `rank` and `suit`. `rank` takes a card and returns the number or letter of the card. `suit` takes a card and returns the suit.

For example:

```
(define four_of_hearts (make-card 4 'h))
(define king_of_diamonds (make-card 'k 'd))
```

```
(rank four_of_hearts) => 4
(rank king_of_diamonds) => k
```

```
(suit four_of_hearts) => h
(suit king_of_diamonds) => d
```

```
(define (rank card)
  (car card))
```

```
(define (suit card)
  (cdr card))
```

(+4)

; only return values, doesn't output them

- (iii) (4 points) Write the function `total` using the new representation of a card. `total` takes a "list of cards" and adds up their value assuming aces count as 11 and there are no jokers.

```
(define (total x)
  (define (total-help LST value)
    (if (null? lst)
```

value

```
(cond ((equal? (rank (car LST)) (member? ('j q k)))
      (total-help (cdr LST) (+ 10 value)))
```

```
((equal? (rank (car LST)) 'a)
      (total-help (cdr LST) (+ 11 value)))
```

```
(else (total-help (cdr LST)
                  (+ (rank (car LST)) value))))))
```

```
(total-help x 0))
```

(+3)

-1
not right way

15/20

args doublet := length

3. (20 points) A word is a doublet of another word if they differ in only one letter. For example, "noise" and "poise" are doublets, "poise" and "posse" are doublets, but "noise" and "posse" are not doublets because they differ in two letters. You are to write the procedure `doublet?` that takes two words and returns #t or #f indicating whether the two arguments are doublets. Doublet words must be the same length. (Hint: you may need a helper function although the problem can be solved without one.)

```
(define (doublet? wd1 wd2)
  (if (not (equal? (length wd1) (length wd2)))
      #f
      (doublet-check wd1 wd2 0)))
```

*legal → #f
but unnecessary*

```
(define (doublet-check wd1 wd2 count)
  (if (equal? wd1 "")
      #f
      (if (= count 1) #t #f)
      (if (not (equal? (first wd1) (first wd2)))
          (doublet-check (bf wd1) (bf wd2) (+ count 1))
          (doublet-check (bf wd1) (bf wd2) count))))))
```

not sure if
length is
count - in
it's called
"count"

```
(define (length wd)
  (define (length-help count wd)
    (if (equal? wd "")
        count
        (length-help (+ 1 count) (bf wd))))
  (length-help 0 wd))
```

4. (10 points) Draw arrows in the following code to demonstrate which variables refer to which definitions. For example:

```
(define (foo x)
  (+ (x) 2))
```

shows that x in the body of the procedure is bound to the formal argument. Note that there is no binding for the formal argument, so no arrow is drawn from it.

- (i) (5 points) Draw arrows to show the binding of each variable in the following examples:

```
(define (bar x)
  ((lambda (x) (* (x) x)) (x)))
```

```
(let ((x 3) (y 2))
  (define (func x) (+ (x) (y)))
  (let ((x 100) (y 200))
    (func (x))))
```

; free until used, will call value from defining environ.

static scoping

defining environment.

- (ii) (5 points) What does the let expression return?

102 ✓

5. (10 points) You are to write a procedure named `agrees?` that takes two arguments:

- 1) a function f that takes one argument
- 2) a list of pairs

The "list of pairs" will be possible values of computing f . In other words, the first value of the pair will be an actual argument and the second value will be a possible return result of the procedure. The `agrees?` procedure will determine whether f applied to the first value in each pair produces a result that matches the second value in the pair. You can think of this procedure as one the readers might construct to test a homework assignment. The `agrees?` procedure should return `#t` or `#f` depending on whether all pairs match. (Example on next page.)

arg	return
-----	--------

```
(define (agrees? f lst)
  (if (null? lst) #t
      (if (and (equal? (f (car lst)) (cadr lst))
                (agrees? f (cdr lst))))
```

*#t
#f*)

don't need if-statement, but ok

For example

```
(agrees? (lambda (x) (* x x))  
         (list (cons 1 1) (cons 3 9))) => #t  
(agrees? (lambda (x) (* x x))  
         (list (cons 2 4) (cons 1 5) (cons 6 36))) => #f  
(agrees? (lambda (x) (* x x)) '()) => #t
```

Write the function agrees?:
